3 **Spatial pattern of arsenic contamination in shallow wells of Bangladesh:**  
4 **regional geology and nonlinear dynamics**

5

6 © Springer-Verlag

5 **Abstract** Since the discovery of large-scale arsenic  
6 contamination of groundwater in Bangladesh more than  
7 a decade ago, studies related to its spatial characteriza-  
8 tion have relied on geostatistical approaches and the  
9 classical notion of linear stochastic dynamics. This study  
10 explores an alternative nonlinear approach, with a  
11 motivation to possibly achieve more cost-effective solu-  
12 tions for Bangladesh. It investigates the existence of  
13 nonlinear deterministic and chaotic dynamic behavior in  
14 the spatial pattern of arsenic contamination in the  
15 shallow wells (depth < 150 m). The database comprises  
16 the nationwide arsenic survey completed in 1999 by the  
17 British Geological Survey (BGS) in collaboration with  
18 the Department of Public Health Engineering (DPHE)  
19 of Bangladesh. Distinction is made in terms of regional  
20 geology (Pleistocene vs. Holocene deposits/Northwest  
21 vs. Southwest) to understand the geologic dependency.  
22 Identification of possible presence of nonlinear deter-  
23 ministic and chaotic patterns is made via the Grassber-  
24 ger-Procaccia correlation dimension algorithm. The  
25 analysis yields correlation dimension values ranging  
26 anywhere from 8 to 11 depending on the region, sug-  
27 gesting that the arsenic contamination in space, from a  
28 chaotic dynamic perspective, is a medium- to high-  
29 dimensional problem. The dimension results also indi-  
30 cate that the spatial dynamics of arsenic may be mod-  
31 erately sensitive to geology, with Pleistocene aquifers  
32 appearing to require a minimum of about two less  
33 dominant processes/variables for its description when  
34 compared to that required by the Holocene aquifers.  
35 Based on these results, a qualitative discussion is also

cast on the potential opportunities offered by a nonlin- 36  
ear deterministic and chaotic dynamic approach towards 37  
improving cost-effectiveness in siting new safe wells. 38

**Introduction** 42

The health risk posed by dissolved arsenic in ground- 43  
water has been reported in many countries around the 44  
world. Concentrations exceeding the World Health 45  
Organization's (WHO) safe limit of 10 parts per billion 46  
(ppb) have been found in, among others, Bangladesh 47  
(Karim 2000), West Bengal in India (Mazumder et al. 48  
1998); Taiwan (Tseng et al. 1968); Vietnam (Berg et al. 49  
2001); Mexico (Del Razo et al. 1990) and regions of the 50  
United States (Welch et al. 2000). However, in terms of 51  
relative proportion of population at risk, arsenic con- 52  
tamination in Bangladesh represents a major calamity in 53  
modern history. It is estimated that about 80% of the 54  
population in Bangladesh (about 103 million) depend on 55  
shallow tube wells that have been excavated at a depth 56  
of less than 150 m (hereafter called 'shallow wells') 57  
(Ahmed 2002, 2003). An exposure distribution study by 58  
Yu et al. (2003) predicts that more than one million-per- 59  
year cases of arsenic-induced ailments are likely to 60  
evolve in the near future. 61

Since 1993, when it was first discovered that the 62  
alluvial Ganges aquifers of Bangladesh were contami- 63  
nated with arsenic, numerous studies have been con- 64  
ducted to better understand the contamination scenario 65  
(e.g., Biswas et al. 1998; Burgess et al. 2000; Bhattach- 66  
arya et al. 2002; Mukherjee and Bhattacharya 2002; 67  
Harvey et al. 2002; van Geen et al. 2002; Meharg and 68  
Rahman 2003; Yu et al. 2003). These studies indicate 69  
that the arsenic contamination is mostly unique to 70  
shallow wells where both the WHO limit and the Ban- 71  
gladesh limit (50 ppb) are consistently exceeded up to a 72

73 depth of 150 m. The first countrywide study towards  
 74 accurate spatial (horizontal) characterization of the  
 75 calamity was conducted in 1998 by the British Geolog-  
 76 ical Survey (BGS) in collaboration with the Department  
 77 of Public Health and Engineering (DPHE) of Bangla-  
 78 desh (hereafter, this survey is referred to as 'BGS-  
 79 DPHE'). This survey revealed that 46% of shallow wells  
 80 exceeded the WHO safe limit, while about 27% exceeded  
 81 the Bangladesh limit.

82 There have been other studies as well that have at-  
 83 tempted a spatial description of arsenic contamination  
 84 by either alluding to the BGS-DPHE (2001) survey for  
 85 benchmarking and/or conducting independent small-  
 86 scale surveys. Notable examples include McArthur et al.  
 87 (2001), van Geen et al. (2003a), Yu et al. (2003), and  
 88 Hossain et al. (2005). Central in all these studies  
 89 addressing the 'spatial' character of arsenic is the use of  
 90 classical geostatistical tools. For example, the BGS-  
 91 DPHE (2001) study reports the application of geosta-  
 92 tistics involving three steps and the assumption that the  
 93 arsenic concentration could be treated as a 'regionalized'  
 94 random variable in space. These three steps are: (1)  
 95 computation and modeling of the variogram; (2) pre-  
 96 diction of concentrations at nonsampled locations by  
 97 kriging; and (3) statistical analysis of errors. Yu et al.  
 98 (2003) used a variogram analysis to characterize the  
 99 spatial variability of arsenic at three spatial scales (1 km,  
 100 10 km and 100 km) nationwide. The study by van Geen  
 101 et al. (2003a) employed simple classical error statistics to  
 102 quantify the vertical (depth) aspect of arsenic variability  
 103 over a 25 km<sup>2</sup> area with high-resolution measurements  
 104 (6,000 wells). More recently, Hossain et al. (2005) have  
 105 also applied the variogram method to quantify the  
 106 spatial variability of arsenic as a function of geology.  
 107 Knowledge of anisotropy due to geology was also used  
 108 therein to understand the implications for enhancing the  
 109 cost-effectiveness of remediation drilling of safe wells on  
 110 a regional basis in Western Bangladesh.

111 While there is no structural, or even philosophical,  
 112 flaw in using the conventional geostatistical approach,  
 113 there is indeed ample room to argue that the geosta-  
 114 tistical treatment of arsenic contamination in space as a  
 115 regionalized random (or stochastic) variable may con-  
 116 stitute only an incomplete analysis of its spatial vari-  
 117 ability (even if system-dependent). Incompleteness can  
 118 potentially arise from the fact that geostatistics often  
 119 fails to recognize the random looking but deterministic  
 120 behavior (hereafter interchanged with 'chaotic behav-  
 121 ior') that may be present due to self-similar (scale-  
 122 invariant) factors in the continuum of the sub-surface.  
 123 For example, it is generally accepted that arsenic in  
 124 groundwaters of Bangladesh is geologic in origin,  
 125 deriving from the sediments transported from the up-  
 126 land Himalayan catchments (BGS-DPHE 2001; McAr-  
 127 thur et al. 2001; Yu et al. 2003). The BGS-DPHE study  
 128 clearly indicated that, contrary to the purely random  
 129 phenomenon observed at the village-scale (< 5 km),  
 130 there exists distinct spatial averages of arsenic contam-  
 131 ination, as indicated by geostatistics, in the regional

scale that is 50–100 km scale at which geologic charac- 132  
 teristics vary in Bangladesh (see Fig. 1). The association 133  
 of low levels of arsenic is found in relatively oxic, up- 134  
 lifted old Pleistocene aquifers, and high arsenic con- 135  
 centrations in reducing young Holocene aquifers 136  
 (Nickson et al. 1998). Most (but not all) of the Pleisto- 137  
 cene deposits are located in the Northern region (com- 138  
 prising Madhupur clay, Barind clay and Alluvial fan 139  
 deposits), while the majority of young Holocene deposits 140  
 are located in the floodplains in the South (Deltaic 141  
 deposits and Alluvial deposits) (see Fig. 1; Alam et al. 142  
 1990). Because Bangladesh is essentially a riverine (and 143  
 dendritic) country with numerous 'small' floodplains, 144  
 and further because the geology shows presence of 145  
 pockets of Holocene-like and Pleistocene-like deposits 146  
 scattered throughout the country (see Fig. 1), there is 147  
 adequate reason to anticipate chaotic behavior in the 148  
 spatial pattern of arsenic contamination. 149

150 However, a more physical argument in favor of  
 151 expecting deterministic chaos in the spatial variation of  
 152 arsenic can be argued as follows. Despite the apparently 152  
 'random' variability observed in the spatial structure of 153  
 arsenic contamination (magnified further at scales 154  
 smaller than 5 km; see BGS-DPHE 2001 and Yu et al. 155  
 2003 for details), field studies so far indicate evidence in 156  
 support of a limited number of competing theories/ 157  
 hypotheses behind the mobilization of arsenic (Burgess 158  
 et al. 2000, 2002; McArthur et al. 2001; Harvey et al. 159  
 2002; van Geen et al. 2003b). Each of these theories can, 160  
 in principle, be mathematically represented as the 161  
 cumulative effect of a finite number of dominant pro- 162  
 cesses modeled by 3 or more partial differential equa- 163  
 tions (note: a minimum of 3 PDEs is required for a 164  
 deterministic system to exhibit chaotic behavior; Hao 165  
 1984). As an example, the theory put forward by Harvey 166  
 et al. (2002) states that groundwater arsenic may have 167  
 increased as a result of increased water withdrawal for 168  
 irrigation. The three core (necessary but not sufficient) 169  
 processes that make up this theory are: (1) groundwater 170  
 extraction by irrigation during winter/nonrainy sea- 171  
 son—a process of porous media flow; (2) recharge of 172  
 groundwater by rainwater, carrying along surface or- 173  
 ganic matter to the subsurface aquifer—a process of 174  
 infiltration (Richards Equation); and (3) microbial 175  
 activity in the aquifer zone leading to reduction in 176  
 conditions for arsenic mobilization—a process involving 177  
 microbial kinetics and diffusion. It may be possible to 178  
 construct similar lines of argument for other competing 179  
 theories/hypotheses to argue that a simple physically 180  
 based arsenic mobilization model (with finite degrees of 181  
 freedom) can produce apparently 'random' spatial pat- 182  
 terns of arsenic contamination in Bangladesh. 183

184 Taking note of the potential limitations of the geo-  
 185 statistical approaches and the possible nonlinear and  
 186 chaotic nature of groundwater flow and transport phe-  
 187 nomena, recent studies have also suggested consider-  
 188 ation of an alternate (non-geostatistical) paradigm for  
 189 analysis of groundwater resources. For example, in a  
 190 review of research on nonlinear deterministic dynamics

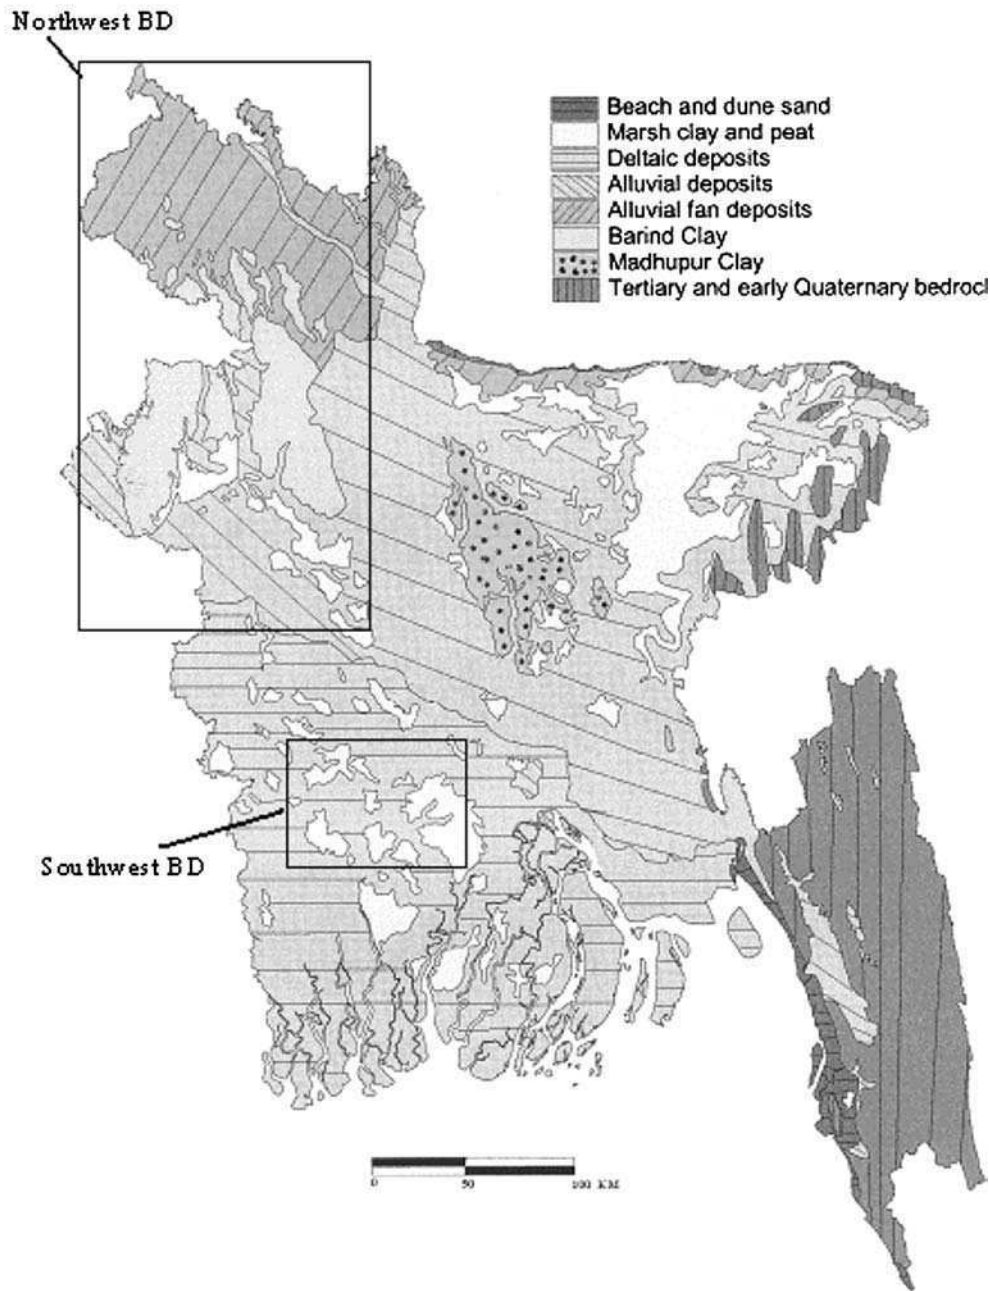

Fig. 1 Geology of Bangladesh (after Alam et al. 1990)

191 in porous media flow, Faybishenko (2004) noted the  
 192 following relevant observation: “For many years the  
 193 general approach to flow investigations in a fractured  
 194 environment has been based on using stochastic meth-  
 195 ods to describe random-looking data sets (e.g., Gelhar  
 196 1993), without considering that deterministic chaotic  
 197 processes could cause apparent randomness of experi-  
 198 mentally observed data.” Similar concerns on the use of  
 199 purely stochastic methods have been echoed by a few  
 200 other studies as well (e.g. Faybishenko 2002; Sivakumar  
 201 2004; Sivakumar et al. 2005), which have indicated the  
 202 potential of nonlinear deterministic approach either

independently or in combination with a stochastic ap-  
 203 proach. 204

Granted that the categorical absence of chaotic  
 205 behavior in groundwater flow and contamination phe-  
 206 nomenon cannot therefore be theoretically established,  
 207 the fundamental question that this study seeks to answer,  
 208 is as follows: What is the degree of nonlinear and chaotic  
 209 behavior observed in the spatial pattern of arsenic con-  
 210 tamination of shallow wells in Bangladesh? The study is  
 211 motivated by the argument that the traditional approach  
 212 of using geostatistics may be inadequate in the context  
 213 of cost-effective solutions (e.g., remediation drilling) for  
 214

215 a resource-poor country like Bangladesh. Traditional  
 216 geostatistical methods, such as kriging, only solve the  
 217 pattern completion problem (i.e., spatial interpolation),  
 218 but not the (complementary) pattern recognition prob-  
 219 lem (e.g., fractals and chaos). As a result, the 'field' of  
 220 arsenic estimated in this fashion from a finite amount of  
 221 field information is subject to uncertainty due to mea-  
 222 surement and sampling errors of in situ arsenic tests. On  
 223 the other hand, a pattern recognition method seeks to  
 224 associate the sampled field with one or more describable  
 225 'memories' (e.g., similar to recognizing a letter from a  
 226 hand-written text) and can be analogous to a nonsto-  
 227 chastic approach, such as the nonlinear deterministic  
 228 dynamic (chaotic) approach.

229 Our investigation of nonlinear deterministic and  
 230 chaotic behavior is, however, not directed towards  
 231 replacement of the conventional geostatistical charac-  
 232 terization techniques, but rather to eventually strengthen  
 233 them by proposing a synergistic use that minimizes the  
 234 individual limitations. Our study represents only a pre-  
 235 liminary exploration of chaotic behavior, and we intend  
 236 to employ in the future appropriately more sophisticated  
 237 methods, in the spirit of increasing cost-effectiveness of  
 238 remediation solutions for Bangladesh. The study is  
 239 based on data from the BGS-DPHE (2001) survey and  
 240 makes geologic distinctions (Holocene vs. Pleistocene;  
 241 Northwest vs. Southwest) to characterize the geologic  
 242 dependency of the chaotic property. Results from this  
 243 study are eventually expected to initiate exploration on  
 244 the usefulness of a nonlinear deterministic and chaotic  
 245 approach in complementing the purely geostatistical  
 246 approach, and, more specifically, to provide a concep-  
 247 tual framework to improve the problem definition for  
 248 questions, such as: (1) what are the implications of the  
 249 chaotic property in improving the cost-effectiveness of  
 250 remediation drilling? and (2) How can guidelines based  
 251 on conventional geostatistical approach be improved for  
 252 a more effective water resources strategy in Bangladesh?

253 The paper is organized as follows. Section 2 presents  
 254 the study region and dataset, while Sect. 3 describes the  
 255 correlation dimension method used for identification of  
 256 chaos. In Sect. 4, we discuss the results and the impli-  
 257 cations for more cost-effective remediation strategies vis-  
 258 à-vis conventional geostatistical approaches. Finally,  
 259 Sect. 5 presents the conclusions and recommendations  
 260 for field-scale investigations to explore further the merit  
 261 of the chaotic approach.

## 262 Study region and data

263 We choose to study the entire region of Bangladesh as  
 264 had been first surveyed by the BGS-DPHE (2001) study  
 265 comprising 3534 wells (see Fig. 1). The dataset is avail-  
 266 able at <http://www.bgs.ac.uk/arsenic/Bangladesh.html>.  
 267 The wells deeper than 150 m (and consistently below the  
 268 safe limits) are excluded from the analysis, thus resulting  
 269 in a set of 3,085 shallow wells. This further implies that  
 270 the vertical variability of arsenic concentration is insig-

nificant compared to its horizontal variability and hence  
 will have negligible effect on the chaotic analysis con-  
 ducted herein. Sample wells are systematically and uni-  
 formly selected with approximately one well per 37 km<sup>2</sup>  
 (~ 6 km×6 km). The arsenic measurements of the BGS-  
 DPHE (2001) survey were based on Atomic Absorption  
 Spectro-photometry (AAS), which is currently consid-  
 ered the most reliable technique for benchmarking arse-  
 nic measurements (Rahman et al. 2002). We assume a  
 minimum detection limit of arsenic concentration as  
 1 ppb and, hence, all nondetection wells are assigned a  
 value of 1 ppb. The advantage of this adjustment is that  
 it preserves the sanity of log-transformation of data that  
 is considered a necessary element, as arsenic concentra-  
 tions are known to vary over 3–4 orders of magnitude in  
 Bangladesh (Yu et al. 2003; Hossain et al. 2004). It must  
 be noted that, due to the spatial resolution of the BGS-  
 DPHE (2001) survey, the study is limited to the scale of  
 about 6–7 km (also note that this is the scale at which  
 villages are clustered under the smallest administrative  
 unit called a 'Union'). As with any type of field inves-  
 tigation, certain limitations (such as inaccessibility of  
 sampling locations and local lack of familiarity with  
 randomized sampling) existed with this BGS-DPHE  
 survey as well. However, in the overall scheme of our  
 investigations, such limitations are considered insignifi-  
 cant due to the fact that the BGS-DPHE survey cur-  
 rently represents the most quality-controlled database of  
 arsenic measurements available countrywide.

To study the role played by geology, we further  
 classified our arsenic database into three categories: (A)  
 Whole Bangladesh (no distinction made in geology); (B)  
 Holocene deposits of Southwest Bangladesh (BD)  
 (geologic distinction—those regions usually high in arse-  
 nic); and (C) Pleistocene deposits of Northwest BD  
 (geologic distinction—those regions usually low in arse-  
 nic). We first defined Western BD as the region west of  
 the *Brahmaputra-Meghna* River system (see Fig. 1). The  
 region is then geographically subdivided into two parts  
 based on major Holocene/Pleistocene differences re-  
 ported by Alam et al. (1990): (B) Southwest BD; and (C)  
 Northwest BD. Hereafter regions A, B and C shall be  
 conveniently interchanged with 'Whole BD', 'Southwest  
 BD (or Holocene deposits)' and 'Northwest BD (or  
 Pleistocene deposits)', respectively. The Northwest BD is  
 defined as the region bound by 24.0°N–26.7°N latitude  
 and 88.0°E–89.5°E longitude representing an area of  
 about 35,000 km<sup>2</sup> with 872 shallow wells (Fig. 1). The  
 Southwest BD is bound by 22.49°N–23.79°N latitude  
 and 89.0°E–90.0°E longitude representing an exclusively  
 Holocene area of about 13,000 km<sup>2</sup> with 848 shallow  
 wells.

## The chaotic approach

Many methods have been formulated for the identifi-  
 cation of chaotic behavior in a data series. One such  
 method used herein is the 'Correlation Dimension' (CD)

method, which attempts to measure the extent to which the presence of a data point affects the position of the other points on the attractor. The concept is analogous to the classical notion of auto-covariance function, with the exception that the dependency of a point in the series (in the continuum of space or time) is cast from the perspective of nonlinear determinism exhibited by a local attractor. The CD method uses the correlation integral or function (Grassberger and Procaccia 1983) for distinguishing between chaotic and stochastic behavior (more specifically, between low-dimensional and high-dimensional systems). The concept of the correlation integral is that even when a process may look irregular (i.e., 'random'), if it comes from deterministic dynamics, it will have a limited number of degrees of freedom equal to the smallest number of first-order differential equations that capture the most important features of the dynamics. For further details on the relevant issues in the application of CD in hydrology and related fields, the reader is referred to the studies by Tsonis et al. (1993), Sivakumar (2000, 2005), and Sivakumar et al. (2002a, b), among others.

It is appropriate to mention, at this stage, that there is a fundamental difference in the manner in which the Grassberger–Procaccia algorithm is employed in the present study when compared to its application in the past. Traditionally, the algorithm has been applied to data series in the continuum of time (e.g. Theiler 1987), whereas herein it is applied to data series in space. While this deviation may raise concerns, which are understandable, we would also like to emphasize that there is no convincing reason to believe that the algorithm cannot be used in the space domain, even involving unequal delay distances. We admit that the phase-space reconstruction for 'irregular-interval data' (regardless of time or space) may have its own limitations, but we believe that such potential limitations alone should not hamper our ability to investigate the usefulness of the algorithm, and this is particularly so when our intention is to primarily conduct a preliminary exploration in a spatial context. In addition, there are two caveats of the Grassberger–Procaccia algorithm that the reader should be forewarned of. The first is causality—there is no reason to expect that causality will hold for spatial series. The second is that there are 1–3 independent variables, rather than 1, affecting arsenic variability in space. Using just the distance as the independent variable, rather than 2 spatial coordinates, implies some type of isotropy in the spatial pattern and may bias results. We believe that the weaknesses of this algorithm, if any, may be revealed in our results, and consequently, we may also employ a more appropriate phase-space reconstruction method in the future.

With the above limitations in mind, each selected well is therefore considered a focal point, and the intra-well distances between all other wells are computed. The arsenic concentrations of each well with respect to the focal well are arranged in the order of increasing intra-well distance. Thus, in essence, Region A (Whole BD)

comprises of 3,085 spatial series, while Region B and C have 848 and 872 spatial series, respectively, each with the same number of data points. The algorithm uses the phase-space reconstruction of these spatial series. For a scalar spatial series  $X_i$ , where  $i = 1, 2, 3, \dots, N$ , (and  $X_i$  is the arsenic concentration at well  $i$ ), the phase-space can be constructed using the method of delays (distances) given by,

$$Y_j = (X_j, X_{j+\tau}, X_{j+2\tau}, \dots, X_{j+(m-1)\tau/\Delta s}), \quad (1)$$

where  $j = 1, 2, \dots, N - (m-1)\tau/\Delta s$ ;  $m$  is the dimension of the vector  $Y_j$ , also called the embedding dimension; and  $\tau$  is the delay distance taken to be some suitable multiple of the average intra-well distances  $\Delta s$ . For an  $m$ -dimensional phase-space, the correlation integral  $C(r)$  is given by (Theiler 1987),

$$C(r) = \lim_{(N \rightarrow \infty)} \frac{2}{N(N-1)} \sum_{i,j} H(r - |Y_i - Y_j|). \quad (2)$$

Here,  $1 \leq i < j \leq N$ ;  $H$  is the Heaviside step function with  $H(u) = 1$  for  $u > 0$  and  $H(u) = 0$  for  $u \leq 0$ , where  $u = r - |Y_i - Y_j|$ , and  $r$  is the radius of sphere centered on  $Y_i$  or  $Y_j$ ; and  $N$  is the number of data points (wells) in the spatial series.

If the spatial series is characterized by an attractor, then for positive values of  $r$ , the correlation integral  $C(r)$  is related to the radius  $r$  by the following relation:

$$C(r) \approx \alpha r^v, \quad (3)$$

where  $\alpha$  is constant; and  $v$  is the correlation exponent or the slope of  $\text{Log } C(r)$  versus  $\text{Log } r$  plot given by:

$$v = \lim_{(r \rightarrow 0, N \rightarrow \infty)} \frac{\text{Log } C(r)}{\text{Log } r}. \quad (4)$$

The slope is generally estimated by a least-squares fit of a straight line over a certain range  $r$ , called the scaling region.

To observe whether or not a chaotic pattern exists in the spatial property of arsenic, the correlation exponent values are plotted against the corresponding embedding dimension values. If the correlation exponent leads to a finite value (i.e., saturation of slopes), then the system is often considered dominated by nonlinear deterministic and chaotic dynamics. If the value of the correlation exponent is small, then the system is generally thought as dominated by a low-dimensional dynamics (spatial) governed by the properties of an attractor. The saturation value of the correlation exponent is defined as the correlation dimension of the attractor of the spatial series. In contrast, for systems dominated by stochastic processes, the correlation exponent is supposed to increase without any bound. While this type of interpretation is generally accepted for distinguishing between chaotic and stochastic behaviors, there may also be certain exceptions, since finite correlation dimensions may also result for stochastic systems with power-law spectra.

439 Some studies have questioned the studies that reported  
 440 existence of chaos in hydrologic data, but such have  
 441 been raised mostly on the ground of data size (e.g.  
 442 Schertzer et al. 2002). While the correlation dimension  
 443 method may indeed possess certain limitations, any  
 444 claim and counterclaim on the presence/absence of  
 445 chaos in a time series needs careful interpretation [see,  
 446 for instance, Sivakumar (2000, 2005) and Sivakumar  
 447 et al. (2002a, b) for details].

448 The CD of an attractor provides information on the  
 449 dimension of the phase-space required for embedding  
 450 the attractor, which, in turn, provides information on  
 451 the number of variables present in the spatial pattern  
 452 of the corresponding arsenic-contaminated hydro-sys-  
 453 tem. According to Fraedrich (1986), the nearest integer  
 454 above the correlation dimension value provides the  
 455 minimum dimension of the phase-space essential to  
 456 embed the attractor, while the value of the embedding  
 457 dimension at which the saturation of the correlation  
 458 exponent occurs provides an upper bound on the  
 459 dimension of the phase-space sufficient to describe the  
 460 motion of the attractor.

## Results and discussion

461

### Correlation dimension analysis

462

Preliminary results of correlation dimension analysis 463  
 reveal insignificant differences among the closely clus- 464  
 tered wells. This is expected, since only the overall var- 465  
 iability of the spatial series is reflected in the CD 466  
 analysis, rather than that between individual and closely 467  
 spaced wells. Hence, for convenience, we demonstrate 468  
 the CD analysis for a finite number of focal wells for 469  
 each region (A, B and C). We select 10 wells for each of 470  
 regions A, B and C. Table 1 summarizes the location of 471  
 each focal well (note: focal wells were also included in 472  
 the CD analyses), its depth and corresponding arsenic 473  
 concentration. Figure 2 shows the relationship between 474  
 correlation function  $C(r)$  and radius  $r$  for the focal well 475  
 A-1 (see Table 1) in region A (no geologic distinction). 476  
 Large scaling regions are observed in Fig. 2, which allow 477  
 us fairly reasonable estimations of the correlation 478  
 exponent. In Figs. 3 and 4, we show similar relationships 479  
 for other focal wells, B-1 and C-1 for regions B (Holo- 480

**Table 1** Description of the 10 selected focal wells for regions A, B and C

Focal well	Location (°)		Depth (m)	Arsenic concentration (ppb)	Comment
	Latitude	Longitude			
Whole BD (Region A)					
A-1	24.303	91.450	35.0	18.7

**Fig. 2** The relationship between  $\text{Log } C(r)$  and radius ( $\text{Log } r$ ) for focal A-1 (region A)

481 cene) and C (Pleistocene), respectively. However, distinctions due to geologic property are hard to establish  
 482 qualitatively in these figures. Since the  $\text{Log } C(r)$  versus  $\text{Log } (r)$  analyses from all other focal wells appear very  
 483 similar, they are not shown herein.

484  
 485  
 486 To analyze the relationship between correlation exponent and embedding dimension, we show Figs. 5, 6  
 487 and 7 for regions A, B and C, respectively. It must be noted, however, that the exact delineation of the scaling  
 488 region (from Figs. 2, 3 and 4, for example) can be a difficult task often requiring semiquantitative methods  
 489 such as visual inspection. Hence, the subsequent estimation of correlation exponent with respect to embed-  
 490 ding dimensions should be assessed as an empirical exercise subject to the limitations of the semiquantitative  
 491 method employed herein. A saturation of the slope  $\text{Log } C(r)/\text{Log } (r)$  is observed, indicating evidence towards  
 492 possible nonlinear deterministic and chaotic dynamic behavior. This saturation value of the correlation  
 493 exponent (also known as Correlation Dimension, CD) appears to show moderate variability across geologic  
 494 property. When no distinction is made in terms of geology, the nationwide CD value appears to lie in the  
 495 ranges of 10–11 while the embedding dimension at which  
 496  
 497  
 498

 500  
 501  
 502  
 503  
 504

this saturation occurs is found to be about 12 (see 505  
 Fig. 5). We take this finding as a preliminary indication 506  
 of the medium-to-high level of dimensionality that exists 507  
 in the mobilization mechanisms of arsenic. Conse- 508  
 quently, it is an indication that a medium-to-large model 509  
 structure (perhaps with 10–12 model parameters) is re- 510  
 quired to adequately capture this spatial variability at 511  
 the regionalized scale ( $\sim 6 \text{ km} \times 6 \text{ km}$ ). Across geologic 512  
 regions, Pleistocene deposits appear to require a mini- 513  
 mum of two less variables/parameters for its spatial 514  
 description than their Holocene counterpart. Also note 515  
 that the CD for Pleistocene region (Northwest BD) 516  
 ranges around 8–9, while Holocene deposits correspond 517  
 much closer to the nationwide value of 10–11. At this 518  
 stage, we speculate that this difference is perhaps due to 519  
 the predominance of oxic conditions in the Pleistocene 520  
 shallow wells that imply the absence of one or more 521  
 arsenic mobilization mechanisms (i.e., no reduction 522  
 mechanism). It is currently unknown as to how these 523  
 saturation values will vary as higher resolution arsenic 524  
 measurements (scales  $< 6 \text{ km} \times 6 \text{ km}$ ) become available 525  
 along with more up-to-date groundwater chemistry 526  
 data. Hence, we stress the need for more detailed 527  
 investigation involving higher resolution data to quan- 528

529 tify more definitively the forcing role played by geology.  
 530 In Table 2, we summarize the mean CD values for the  
 531 selected 10 focal points over each region.

532 It is appropriate, at this stage, to highlight spatial  
 533 variability analyses recently reported by Hossain et al.  
 534 (2005) on the basis of a purely geostatistical framework  
 535 (variogram analyses). Hossain et al. (2005) reported  
 536 that regional anisotropy in the spatial dependence of  
 537 arsenic for Northwest region of Bangladesh was found

538 to be stronger than that in the Southwest. The corre-  
 539 lation length for arsenic concentration in the East-  
 540 West direction of Northwest Bangladesh (i.e., across  
 541 major river floodplains, Fig. 1) was found to be almost  
 542 twice (158.80 km) that of the North-South direction  
 543 (along the major axis of Pleistocene deposits)  
 544 (78.21 km). For the Southwest region, the ratio of  
 545 East-West to North-South correlation lengths ranged  
 546 from 1.40 to 1.51.

547 Implications of chaotic behavior for cost-effective siting  
548 of remediation wells

549 For siting of new (safe) wells, it is currently considered a  
550 very expensive, and even almost-impossible, task to  
551 reconcile the need for detailed knowledge of hydroge-  
552 ology with the tremendous spatial variability (centime-  
553 ters vertically; meters horizontally) that is observed in  
554 the Bangladesh sediments. Nevertheless, detailed field  
555 studies can always lead to some useful ‘rules of thumb’  
556 for well-siting at the village level. The indications of such  
557 an approach can be found in Hossain et al. (2004).  
558 However, initial experiences of the BGS-DPHE (2001,  
559 see page 240) over a small study region have exemplified  
560 the difficulty in accurately quantifying the likelihood of  
561 identifying ‘uncontaminated wells’ from a geostatistically  
562 derived spatial map of arsenic contamination. A major  
563 inadequacy of geostatistical approaches, in our opinion,  
564 arises from the observation that a geostatistically iden-  
565 tified (i.e., ‘kriged’) drilling location of a remediation  
566 well in the neighborhood of a contaminated well is  
567 associated with an uncertainty (equivalent to the mini-  
568 mized error variance). In Bangladesh, where public  
569 health is at risk, such uncertainty needs to be reduced  
570 and, hence, conventional geostatistical approaches (such  
571 as kriging) should be explored for ‘enhancement’ with  
572 the less conventional paradigms such as the nonlinear  
573 deterministic chaos theory to minimize the limitations.

574 Let us now consider, as an example, the recent report  
575 on implementing a safe water supply program for Sri-

nagar—a sub-district of Bangladesh comprising about 576  
30,000 (mostly rural) people (Hoque et al. 2004). Expe- 577  
rience from this program clearly recommended that, for 578  
arsenic-affected areas, a cluster-based piped water sys- 579  
tem be given proper consideration when selecting 580  
appropriate water options rather than household-based 581  
options or the development of new low-cost options (e.g. 582  
filters, rain-water harvesting etc.) (Hoque et al. 2004). 583  
To effectively construct a cluster-based piped water 584  
system, a network of wells would need to be drilled and 585  
centrally connected through a piped network in a fash- 586  
ion that the overall quality of water being pumped is 587  
within the Bangladesh safe limit of 50 ppb for arsenic. 588  
This requires drilling the maximum number of safe 589  
wells, although a few unsafe wells may also be accept- 590  
able. For cost-effective implementation of this program, 591  
there are now two competing aspects interacting at the 592  
level of risk management and decision-making: (1) 593  
alternative but safe drinking water supply needs to be 594  
ensured rapidly; and (2) remediation drilling should be 595  
preferably shallow (given that deep-well drilling is a 596  
time-consuming and very costly option) and planned in 597  
surrounding locations that are known to be ‘probabi- 598  
listically’ low in arsenic. 599

Under such a situation, a chaotic approach has the 600  
potential to augment the geostatistical approach. The 601  
chaotic approach can identify the minimum number of 602  
model (physical or black-box) parameters required to 603  
adequately model the spatial variability of arsenic in 604  
space for the affected region that has already been 605  
mapped for its CD value. One suggested example is the 606  
use of a neural-network (NN) model with the number of 607  
nodes equaling the number of variables (embedding 608  
dimensions) obtained from the CD analysis that spa- 609  
tially ‘forecasts’ safe zones. The inputs to the NN-cha- 610  
otic model would be the arsenic concentration of the 611  
focal well (point of application) and the distance from 612  
the well (i.e., point of prediction). This NN-chaotic 613  
model can then be used to identify the spots that are 614  
likely to be safe in arsenic concentration (in recognition 615  
of the self-similarity) and subsequently used as an 616  
additional constraint to the geostatistical siting of wells 617

Table 2 Summary of correlation dimension value for regions A, B and C

	Correlation dimension	
	Min	Max
Region A	10	11
Region B (Holocene)	10	11
Region C (Pleistocene)	8	9

618 (i.e., both kriging and the NN-chaotic model should  
 619 agree on the location's safe/unsafe likelihood). Despite  
 620 the traditional criticism of neural-network approaches  
 621 (or any 'time series' approach, for that matter) as lack-  
 622 ing potential to promote the scientific insight of a nat-  
 623 ural phenomenon, recent work indicates that substantial  
 624 understanding has been gained in designing its archi-  
 625 tecture (nodes and hidden layers) based on the physical  
 626 process it models [see for example: Sudheer and Jain  
 627 (2003) and Jain et al. (2004) for river flow].

628 Currently, there are a number of maps available that  
 629 characterize the probability of arsenic contamination in  
 630 nonsampled regions based on kriging (see BGS-DPHE  
 631 2001 and McArthur et al. 2001, for example). Hence, a  
 632 combination of geostatistics with a chaotic dynamic  
 633 approach can intuitively be expected to refine the safe  
 634 drilling spots with considerably lower probability of  
 635 failure (i.e., by reducing the number of false hopes and  
 636 false alarms) than what would have otherwise been  
 637 indicated by kriging alone. Although it remains to be  
 638 seen if there exists a (suggested) physical connection  
 639 between the minimum number of NN nodes and the  
 640 minimum embedding dimension from the CD method at  
 641 the region of application [see, however, Sivakumar et al.  
 642 (2002) for such a connection for river flow], the sug-  
 643 gession, which has insignificant start-up costs compared  
 644 to laboratory studies, is certainly worth investigating  
 645 until proven wholly ineffective.

## 646 Conclusion

647 This paper presented a preliminary investigation of the  
 648 existence of nonlinear deterministic and chaotic behavior  
 649 in arsenic contamination in shallow tube wells of Ban-  
 650 gladesh. The correlation dimension method revealed  
 651 convincing medium-to-high dimensional chaotic pattern  
 652 with a countrywide dimension value ranging between 8  
 653 and 11. The minimum number of variables and, hence,  
 654 the number of dominant processes required to model the  
 655 spatial variability of arsenic were also identified. It ap-  
 656 peared that chaotic behavior of arsenic is moderately  
 657 sensitive to geology (Holocene vs. Pleistocene). The study  
 658 indicated that Pleistocene aquifers would require two less  
 659 minimum number of variables for its spatial description  
 660 compared to the Holocene counterpart. However, higher  
 661 resolution data may be required to explore this issue  
 662 further. Finally, the paper discussed the potential  
 663 opportunities offered by the chaotic approach towards  
 664 better cost-effective remediation strategies than that  
 665 possible by a purely geostatistical framework.

666 As part of a proposed (and needed) 'enhancement' of  
 667 geostatistical approaches for spatial characterization  
 668 towards increasing cost-effectiveness, we list the follow-  
 669 ing as natural extensions to this study: (1) Investigate the  
 670 scale-invariant or fractal behavior of arsenic with high-  
 671 resolution data, with due consideration for the possible  
 672 influence of (small) data size, thresholds and presence of  
 673 zeros (or any other single value) on the outcomes of

fractal/chaos methods (e.g., Harris et al. 1997; Sivaku- 674  
 mar 2001); (2) Consider the effects of depth of wells on 675  
 chaotic characterization and explore fuzzy logic ap- 676  
 proaches of membership functions (e.g., Klir and Yuan 677  
 1995) to categorize wells as deep or shallow; and (3) 678  
 Study the impact of measurement error on the identifi- 679  
 cation of chaotic behavior [see, for example, Sivakumar 680  
 et al. (1999)] using the semiquantitative field kits (Rah- 681  
 man et al. 2002). 682

Among the suggested extensions, (3) has particular 683  
 significance to increase cost-effectiveness of (and reduc- 684  
 ing risks for) siting of safe shallow wells through our 685  
 proposed paradigmatic approach (geostatistical-cum- 686  
 chaotic). The majority of arsenic measurements in 687  
 Bangladesh on a large scale (totalling about 1.3 million 688  
 wells) are available from the cheap Field Kits (FK) 689  
 (Rahman et al. 2002). Although FK measurements are 690  
 subject to large errors with a highly complex error 691  
 structure, Hossain et al. (2005) have demonstrated that 692  
 FK measurements can still adequately characterize the 693  
 modal depth (depth of highest arsenic contamination) 694  
 for shallow wells. This probably indicates that the 695  
 database of FK-arsenic measurements that are currently 696  
 available countrywide may indeed be sufficient to char- 697  
 acterize the probable depth of highest arsenic contami- 698  
 nation for local regions, even though the modal arsenic 699  
 contamination rate (i.e., "highest fraction of contami- 700  
 nated wells") may have large errors. Hence, one current 701  
 challenge is to investigate the efficacy of using FKs for 702  
 mapping the chaotic behavior of arsenic and (otherwise) 703  
 propose new desired performance levels for FKs that 704  
 would make them as useful as AAS method in our 705  
 proposed geostatistical-cum-chaotic siting of new wells 706  
 (see Sect. 4B). Work is ongoing in this direction, and we 707  
 hope to report the details in the near future. 708
